

Adaptive Clustering for Mobile Wireless Networks

Chunhung Richard Lin and Mario Gerla

Abstract— This paper describes a self-organizing, multihop, mobile radio network which relies on a code-division access scheme for multimedia support. In the proposed network architecture, nodes are organized into nonoverlapping clusters. The clusters are independently controlled, and are dynamically reconfigured as nodes move. This network architecture has three main advantages. First, it provides spatial reuse of the bandwidth due to node clustering. Second, bandwidth can be shared or reserved in a controlled fashion in each cluster. Finally, the cluster algorithm is robust in the face of topological changes caused by node motion, node failure, and node insertion/removal. Simulation shows that this architecture provides an efficient, stable infrastructure for the integration of different types of traffic in a dynamic radio network.

Index Terms—CDMA, mobile computing, multimedia, packet radio, personal communication systems, quality of service, real-time traffic, routing, spread spectrum, wireless networks.

I. INTRODUCTION

PERSONAL communications and mobile computing require a wireless network infrastructure which is rapidly deployable, possibly multihop, and capable of multimedia service support. The first infrastructure of this type was the packet radio network (PRNET), developed in the 1970's to address the battlefield and disaster recovery communication requirements [16], [17]. PRNET was totally asynchronous, and was based on a completely distributed architecture. It handled datagram traffic reasonably well, but did not offer efficient multimedia support. Recently, under the WAMIS (Wireless Adaptive Mobile Information Systems) [1] and Glomo ARPA programs, several mobile, multimedia, multihop (M^3) wireless network architectures have been developed, which require some form of synchronous, time-division infrastructure. The synchronous time frame leads to efficient multimedia support implementations. However, it introduces more complexity, and is less robust in the face of mobility and channel fading. Clearly, there are complexity versus performance tradeoffs in introducing various degrees of synchronization into the network, from the completely asynchronous PRNET to the tightly synchronized cluster TDMA solution proposed in [7]. In this paper, we will evaluate these tradeoffs, and will,

Fig. 1. Conventional cellular networks (single hop).

in fact, propose a scheme with an intermediate degree of synchronization.

Another important wireless network feature addressed in this paper is multihopping, i.e., the ability of the radios to relay packets from one to another without the use of base stations. Most of the nomadic computing applications today are based on a single-hop radio connection to the wired network (Internet or ATM). Fig. 1 shows the cellular model commonly used in the wireless networks. *A*, *B*, *C*, and *D* are fixed base stations connected by a wired backbone. Nodes 1–8 are mobile nodes. A mobile node is only one hop away from a base station. Communications between two mobile nodes must be through fixed base stations and the wired backbone.

In parallel with (and separately from) the single hop cellular model, another type of model, based on radio-to-radio packet multihopping, has been emerging to serve a growing number of applications which rely on a rapidly deployable, wireless infrastructure. The classic examples are battlefield communications and (in the civilian sector) disaster recovery (fire, earthquake) and search and rescue. A recent addition to this set is the ad hoc personal communications network, which could be rapidly deployed on a campus, for example, to support collaborative computing and access to the Internet during special events (concerts, festivals, etc.). Multihopping through wireless repeaters strategically located on campus permits us to reduce battery power and to increase network capacity. More precisely, by carefully limiting the power of radios, we conserve battery power. Furthermore, we also cause less interference to other transmissions further away; this gives the additional benefit of "spatial reuse" of channel spectrum, thus increasing the capacity of the system.

Interestingly, the multihop requirement may also arise in cellular networks. If a base station fails, a mobile node may not be able to access the wired network in a single hop. For example, in Fig. 2, if base station *B* fails, node 4 must access base stations *A* or *C* through nodes 2 or 5 which act as wireless multihop repeaters.

In this paper, we consider a networking environment in which the users are mobile, the topology changes, interference occurs when multiple transmissions take place over (possibly

Fig. 2. A multihop situation occurs when base station *B* fails.

different) links on the same or different codes, real-time multimedia traffic must be supported as well as datagram traffic, there is no stable communication infrastructure, and there is no central control. The kind of application scenario that motivates this research includes many that require instant infrastructure network support and multimedia network support. These include military applications (special operations, battlefield scenarios, etc.), disaster relief (fire, earthquake, flood), law enforcement situations, short-term scenarios such as public events, etc.

For the above environment and scenarios, we develop an architecture and networking algorithms which support a rapidly deployable radio communications infrastructure. The network provides guaranteed quality of service (QoS) to real-time multimedia traffic among mobile users without requiring a fixed infrastructure (e.g., no base station). The last comment is worth emphasizing since much of the research in wireless communications has exploited the existence of "central" control of base stations. We deal with no such central system support in this research.

The paper is organized as follows. Section II presents the network architecture. Based on this architecture, Section III introduces the protocol for packet transmission. Section IV describes the QoS routing. Section V shows some system performance, and Section VI concludes the paper.

II. THE MULTICLUSTER ARCHITECTURE

A major challenge in multihop, multimedia networks is the ability to account for resources so that bandwidth reservations (in a deterministic or statistical sense) can be placed on them. We note that in cellular (single-hop) networks, such accountability is made easy by the fact that all stations learn of each other's requirements, either directly or through a control station (e.g., base station in cellular systems). This solution can be extended to multihop networks by creating clusters of radios in such a way that access can be controlled and bandwidth can be allocated in each cluster. The notion of cluster also has been used in earlier packet radio nets, but mainly for hierarchical routing rather than for resource allocation [3], [4].

Most hierarchical clustering architectures for mobile radio networks are based on the concept of *clusterhead* [3], [4], [7]. The clusterhead acts as a local coordinator of transmissions within the cluster. It differs from the base station concept in current cellular systems in that it does not have special hardware and, in fact, is dynamically selected among the set of stations. However, it does extra work with respect to ordinary stations, and therefore it may become the bottleneck of the cluster. To overcome these difficulties, in our approach, we

eliminate the requirement for a clusterhead altogether, and adopt a fully distributed approach for cluster formation and intra-cluster communications [13], [14].

The objective of the proposed clustering algorithm is to find an interconnected set of clusters covering the entire node population. Namely, the system topology is divided into small partitions (*clusters*) with independent control. A good clustering scheme will tend to preserve its structure when a few nodes are moving and the topology is slowly changing. Otherwise, high processing and communication overheads will be paid to reconstruct clusters. Within a cluster, it should be easy to schedule packet transmissions and to allocate the bandwidth to real-time traffic. Across clusters, the spatial reuse of codes must be exploited. Since there is no notion of clusterhead, each node within a cluster is treated equally. This permits us to avoid vulnerable centers and hot spots of packet traffic flow.

A. The Clustering Algorithm

In order to support multimedia traffic, the wireless network layer must guarantee QoS (bandwidth and delay) to real-time traffic components. Our approach to provide QoS to multimedia consists of the following two steps: 1) partitioning of the multihop network into clusters, so that controlled, accountable bandwidth sharing can be accomplished in each cluster; and 2) establishment of virtual circuits with QoS guarantee. In this section, we describe the implementation of both steps in the multicenter architecture.

The objective of the clustering algorithm is to partition the network into several clusters. Optimal cluster size is dictated by the tradeoff between spatial reuse of the channel (which drives toward small sizes) and delay minimization (which drives toward large sizes). Other constraints also apply, such as power consumption and geographical layout. Cluster size is controlled through the radio transmission power. For the cluster algorithm, we have so far assumed that transmission power is fixed and is uniform across the network.

Within each cluster, nodes can communicate with each other in at most two hops. The clusters can be constructed based on node ID. The following algorithm partitions the multihop network into some nonoverlapping clusters. We make the following operational assumptions underlying the construction of the algorithm in a radio network. These assumptions are common to most radio data link protocols [3], [4], [6], [7].

- A1) Every node has a unique ID and knows the ID's of its one-hop neighbors. This can be provided by a physical layer for mutual location and identification of radio nodes.
- A2) A message sent by a node is received correctly within a finite time by all of its one-hop neighbors.
- A3) Network topology does not change during the algorithm execution.

Our distributed clustering algorithm is shown in Fig. 3. We can find from this algorithm that each node only broadcasts one *cluster* message before the algorithm stops, and the time complexity is $O(|V|)$ where V is the set of nodes. The

        broadcast cluster(my_id, my_cid);
         $\Gamma = \Gamma - \{my\_id\}$ ;
      }
    }
  }
  if ( $\Gamma == \emptyset$ ) stop;
}

```

Fig. 3. Distributed clustering algorithm.

Fig. 4. System topology.

clustering algorithm converges very rapidly. In the worst case, the convergence is linear in the total number of nodes. Consider the topology in Fig. 4. After clustering, in Fig. 5, we can find six clusters in the system, which are $\{1, 2\}$, $\{3, 4, 11\}$, $\{5, 6, 7, 8, 9\}$, $\{10, 12, 13\}$, $\{14, 15, 16, 17\}$, $\{18, 19, 20\}$. To prove the correctness of the algorithm, we have to show that: 1) every node eventually determines its cluster; 2) in a cluster, any two nodes are at most two hops away; and 3) the algorithm terminates.

Lemma 1: Every node can determine its cluster and only one cluster.

Proof: The cluster ID of each node is either equal to its node ID or the lowest cluster ID of its neighbors. Every node must have its cluster ID once it becomes the lowest ID node in its locality. This cluster ID will be broadcast at this time, and will not be changed before the algorithm stops. Hence, every node can determine its cluster and only one cluster.

Lemma 2: In a cluster, any two nodes are two hops away at most.

Fig. 5. Clustering.

Proof: Assume any node, say x , whose cluster ID ($cid(x)$) is not equal to node ID ($nid(x)$). From this algorithm, there must exist a neighbor of x , say y , $cid(y) = nid(y) = cid(x)$. Thus, the hop distance between x and y is one. So for any two nodes x and x' , $cid(x) = cid(x') = nid(y)$, the hop distance between x and x' is no more than two.

Theorem 1: Eventually the algorithm terminates.

Proof: Since every node can determine its cluster (Lemma 1), the set Γ will eventually become empty. Thus, the algorithm will terminate.

Theorem 2: Each node transmits only one message during the algorithm.

Proof: A node broadcasts messages only at the time it becomes the local minimal ID node ($\min(\Gamma) == my_id$), and the cluster ID which is broadcast will not be changed before the algorithm stops). Thus, only one message is sent out before the algorithm stops.

Theorem 3: The time complexity of the algorithm is $O(|V|)$.

Proof: From the distributed clustering algorithm, each message is processed by a fixed number of computation steps. From Theorem 2, there are only $|V|$ messages in the system. Thus, the time complexity is $O(|V|)$.

As we shall see in the following experiments, the transmission power determines the network topology, and therefore has a direct impact on the performance of the cluster solution. If the power is large, the average hop length between source-destination (SD) pairs is small. Thus, the system throughput will tend to increase. However, higher interference due to large power will tend to limit the throughput. If we decrease the power, the interference is also decreased. However, since the average hop length between SD pairs is increased, the network will accumulate more packets among the store-and-forward paths. Congestion control becomes more critical in this situation. Clearly, it is important to choose a suitable power level in order to get high system performance.

We simulate the clustering algorithm by placing N nodes randomly in a 100×100 area, and we measure some of its properties. We assume that two nodes can hear each other if their distance is within a predefined transmission range. We begin studying the impact of transmission range on connectivity. The connectivity is defined as the fraction of node pairs which can communicate through single or multiple hops. We assume an ideal network model where a link can be established between any two nodes within transmission

average connectivity

Fig. 6. Connectivity property.

average order of repeaters

Fig. 7. Average order of repeaters.

range of each other, and where a path can always be found (by the routing algorithm) between two nodes connected by a chain of links. Several random deployments of the N nodes are examined for each transmission range. Each deployment yields a different value of connectivity. In Fig. 6, we report the average connectivity. From Fig. 6, we note that in order to guarantee that all nodes can communicate with each other, the transmission range should be more than 30 for $N = 40$ and more than 40 for $N = 20$.

Next, we study the characteristics of the clusters generated by the algorithm. In the multicluster architecture, *repeaters*, for example node 2 in Fig. 5, relay packets from one cluster to another. Every repeater is time shared among the set of adjacent clusters, that is, its spreading code must be transmitted to these clusters. So, the *order* of a repeater (i.e., how many clusters it can access, for example, the order of node 2 is two and the order of node 6 is four) should be small in order to maintain efficient operation, with as few code changes as possible (the minimal order of a repeater is two). Fig. 7 shows the average order of repeaters versus the transmission range. From this figure, we find that the typical order of the repeaters is either two or three based on this clustering algorithm.

Since the topology in WAMIS is dynamically changed, the reliability of packet routing is important to guarantee the integrity of network services. Thus, the existence of at least one path between a pair of nodes is required. The number of repeaters will affect the number of paths. Namely, the larger

number of repeaters

Fig. 8. Number of repeaters.

Fig. 9. Reclustering.

the fraction of nodes which are repeaters, the larger the number of alternate paths. In Fig. 8, we note that more than 50% of nodes are repeaters if the transmission range is over the interval (30, 80).

B. Cluster Maintenance in the Presence of Mobility

In the *dynamic radio network*, 1) nodes can change location, 2) nodes can be removed, and 3) nodes can be added. A topological change occurs when a node disconnects and connects from/to all or part of its neighbors, thus altering the cluster structure. System performance is affected by frequent cluster changes. Therefore, it is important to design a cluster maintenance scheme to keep the cluster infrastructure as stable as possible. In this respect, the proposed cluster algorithm is more robust than the one reported in [7] since there are fewer restrictions on clusters. The cluster maintenance scheme was designed to minimize the number of node transitions from one cluster to another.

Consider the example shown in Fig. 9(a). There are five nodes in the cluster and the hop distance is no more than two. Because of mobility, the topology changes to the configuration shown in Fig. 9(b). At this time, $d(1,5) = d(2,5) = 3 > 2$, where $d(i,j)$ is the hop distance between nodes i and j . So the cluster needs to be reconfigured. Namely, we should decide which node(s) should be removed from the current cluster. We let the highest connectivity node and its neighbors stay in the original cluster, and we remove the other nodes. Recall that each node only keeps the information of its "locality," that is, one- and two-hop neighbors. Upon discovering that a member, say x , of its cluster is no longer in its locality, node y should

Fig. 10. Stability of the multicluster architecture.

check if the highest connectivity node is a one-hop neighbor. If so, y removes x from its cluster. Otherwise, y changes cluster.

Two steps are required to maintain the cluster architecture:

Step 1: Check if there is any member of my cluster that has moved out of my locality.

Step 2: If Step 1 is successful, decide whether I should change cluster or remove the nodes, not in my locality, from my cluster.

Consider the example in Fig. 9(b). Node 4 is the highest connectivity node. Thus, node 4 and its neighbors $\{1, 2, 3\}$ do not change cluster. However, node 5 should either join another cluster or form a new cluster. If a node intends to join a cluster, it has to check first if all members of this cluster are in its locality. Only in this case can it join the cluster.

We measure the stability of the multicluster architecture by counting how many nodes immigrate from one cluster to another (or form a new cluster) within a 100 ms interval. Fig. 10 shows the stability of the cluster maintenance algorithm. In our simulation, every 100 ms, each node moves in a direction uniformly distributed over the interval $(0, 2\pi)$, covering a distance of $(0, 3)$ ft. From Fig. 10, note that the average number of nodes which change clusters per 100 ms is relatively small over the $(40, 50)$ transmission range (which is the region of interest). Note also that our cluster maintenance scheme based on node connectivity is more stable than the “clusterhead” scheme reported in [7].

C. Code Assignment

Each node has a transceiver which can either transmit or receive at any given time. In the spread-spectrum code-division system, the receiver should be set to the same code as the designated transmitter. For simplicity (and to be conservative), we assume no capture. That is, if two or more transmissions interfere at the same receiver, none is received, regardless of the code. We assume that there is a small set of “good” spread-spectrum codes which are low cross correlation. Since the number of codes we can use is very limited, the spatial reuse of codes will be important [11]. Thus, each cluster is assigned a single code which is different from the codes using in the neighbor clusters. The problem of the code selection can be formulated as a graph-coloring problem, and has been extensively studied in [11].

There are three options for using the dedicated code within a cluster.

- 1) Receiver-based code assignment: Every node within a cluster is assigned a common receiving code. All neighbor nodes send packets to a node using its code. In this scheme, a receiver only listens to one code, but both intercluster and intracluster collisions can occur.
- 2) Transmitter-based code assignment: Within a cluster, every node uses a common transmitting code so that there is no intercluster collision. If no two nodes in a cluster are transmitting simultaneously, there will be no intracluster collision.
- 3) Another approach is to assign a common codes to all transmitter-receiver pairs within a cluster. This code assignment requires that some other codes be assigned for intercluster communications.

Following [11], we use transmitter-based code assignment. Receiver-based assignment cannot avoid intercluster collision, and internal pair code assignment needs extra codes for inter-cluster communications. Since there is no intercluster collision with the chosen scheme, we only need to be concerned with collision avoidance within a cluster. Based on transmitter-based code assignment, when a node is not in transmitting mode, it randomly selects and listens to one of the codes used by its neighbors. In Fig. 5, for example, node 6 will randomly listen to the codes in C_{10}, C_{14}, C_{18} , and C_5 .

D. Network Initialization

Initialization is carried out using a common “control” code in the same way as described in [7]. A node which does not yet belong to a cluster listens to the control code until timeout. Then it transmits its own ID (using the control code), and repeats the procedure until it hears from one of the neighbors. Channel access in this phase is CSMA. This basic communication facility allows nodes to organize themselves in clusters following the algorithm just described. Once a cluster is formed, the cluster leader communicates with the neighbors (using the control code) to select the codes. Only when the code assignment is completed (i.e., each cluster has been assigned its code) can user data be accepted by the nodes and transmitted in the network.

III. TRANSPORT PROTOCOLS

In this section, we introduce the medium access control (MAC), link, and network layer protocols (with the exception of routing, which is discussed in Section IV). The aim of our design is to support integrated traffic (i.e., datagram and real time) efficiently. We will assume fixed packet size through the paper.

A. Channel Access Scheme

Since our system assumes a common transmitting code in each cluster, there is no intercluster collision. The receiver must tune to the transmitter’s code to receive the packet. Since the distance between any two nodes in the same cluster is at most two hops, it is relatively easy to maintain time

Fig. 11. Channel access frame within a cluster.

Fig. 12. Implicit acknowledgment scheme.

(i.e., slot) synchronization within each cluster. So, the channel will be assumed slot synchronized. It must be noted that synchronization is required only within a cluster. This is much easier than maintaining slot synchronization across the entire network as in [7] and [14].

Within each cluster, the MAC layer is implemented using a TDMA scheme. Time is divided into slots which are grouped into frames. In Fig. 11, assume that there are n nodes in a cluster. Each node is assigned a slot to transmit either control (such as ACK's and connectivity) or data information. In each frame, a free slot is reserved for a new node joining the cluster. Using the control code, the nodes in the cluster take turns to transmit periodically in the free slot their cluster and code information for the purpose of "attracting" new nodes or migrant nodes. When a node decides to join a cluster, the node listens to the channel for a period of time, and then uses this free slot to transmit packets temporarily. Since cluster switches are infrequent, one free slot will suffice. The frame is readjusted after each join/leave.

B. Acknowledgment for Datagram

Datagram traffic is error sensitive. Thus, it is important to design a reliable transmission for datagrams. In addition to forward error correction (FEC) at the link level and end-to-end (TCP) acknowledgments, we have a link level acknowledgment scheme which is conflict free. As mentioned earlier, each cluster has a dedicated code for transmission. Since every node can only transmit packets in its assigned TDMA slots, we use an implicit acknowledgment scheme. Namely, upon receiving a packet successfully, the *intended receiver*, the node to which a packet is destined, piggybacks the ACK on its data packet at its assigned slot. The transmitter listens to the receiver's slot and code. If a time out occurs, it retransmits the data packet. Fig. 12 illustrates this implicit ACK scheme. Node x uses code a to transmit its packet to y , and then listens to code b for ACK. Node y receives the packet successfully. When its transmitting slot comes, y piggybacks an ACK for x on the packet which is transmitted to z .

C. Bandwidth Reservation for Virtual-Circuit Traffic

A real-time connection is set up using a fast reservation approach. Namely, we assume that real-time packets arrive at

constant time intervals. The first data packet in the multimedia stream makes the reservations along the path. Once the first data packet is accepted on a link, a transmission window is reserved (on that link) at appropriate time intervals for all of the subsequent packets in the connection. The window is released when idle for a prespecified number of cycles. Conceptually, this scheme is an extension of PRMA (packet reservation multiple access) [8] to the multihop environment.

Each real-time connection is assigned to a VC (virtual circuit). The VC is an end-to-end path along which slots have been reserved. As we shall later see, the path and slots of a VC may change dynamically during the lifetime of a connection due to mobility. Each node schedules each of its slots to transmit either datagram or VC traffic. Since real-time traffic (which is carried on a VC) needs guaranteed bandwidth during its active period, each node has to reserve its own slots to the VC at connection setup time.

When a node intends to set up a VC to its neighbor, it transmits the first packet of the session as a datagram packet in its TDMA slot. After successfully receiving the packet, the intended receiver will set up the reservation for receiving the next packet since the next transmission time is piggybacked on the current packet. Since the sender always uses the same code to transmit packets, the intended receiver only needs to lock on that code when the reserved slot comes. If the link is not broken due to mobility, the subsequent packets will be received successfully (assuming perfect channel). No ACK is necessary.

Let *CYCLE* be the maximum interval tolerated between two real-time packets. The first packet of a real-time session is treated as a data packet and is transmitted using TDMA. A real-time source schedules its next transmission after a time *CYCLE* following a successful transmission, and piggybacks the reservation with the current packet transmission. Fig. 13 shows that node i successfully transmits the first real-time packet, and it reserves the time slot for the real-time session. The receiver has to listen to the sender's transmitting code when the reserved time slot comes. So, for real-time sources, transmission is always collision free and the maximal delay is guaranteed. At the end of the real-time session (i.e., the reservation field is set to zero), the reservation is automatically canceled.

Because of the limitation of node bandwidth in a cluster, the number of real-time sessions which can pass through a node is restricted. Slots which are not reserved by voice traffic are accessed according to a TDMA protocol. Datagram packets become backlogged when real-time traffic starts building up. Consider the case when the bandwidth of a node is completely used by real-time session. That is, there are $\lfloor (CYCLE / ((n+1) \cdot t)) \rfloor$ real-time sessions (see Fig. 13) over a node, where n is the number of members in the cluster and t is the packet transmission time. No other source can construct a VC which passes through the saturated node until one of the VC's over the saturated node ends its transmission and bandwidth becomes available. To avoid datagram traffic lockout, a limit is imposed on the maximum number of real-time sessions on

Fig. 13. Bandwidth reservation.

Fig. 14. Average number of links between an adjacent cluster pair.

each node. Also, it is assumed that *CYCLE* time is much longer than frame time, so that a node can transmit real-time and datagram packets in alternate frames.

D. Mobility

As nodes move from one cluster to another, it is easy for a node to join a cluster. First, the node does not destroy the target cluster structure. Rather, it changes its own cluster ID, using the free slot to transmit packets in the new code. After a predefined time period (for example, 100 ms in our system), the nodes in a cluster will recompute the new TDMA frame format. In the same way, if a node is removed from a cluster, the frame is reduced. In the rare event that more than one node joins a cluster, collision may occur at the free slot. Using random retransmission and backoff, eventually all new nodes can make themselves known, and a new frame format is computed accordingly.

Typically, multiple links exist between adjacent clusters (see Fig. 14). Therefore, as a node moves, the connectivity between clusters will not change very rapidly. This characteristic is important for the rerouting of VC's following node movements. When a new link has to be built for an existing real-time session due to topological change, the reservation procedure discussed in the previous section must be reexecuted on the new route. More precisely, following the "fast VC reservation" concept introduced in [7], the first packet to be rerouted will trace the new path and make reservations on it. If bandwidth is not adequate on the new path, the connection is dropped. Alternatively, if layered coding is used, low priority packets

can be dropped, as described in [7], thus reducing the required bandwidth, and making the new path feasible [7].

IV. QoS ROUTING

Multimedia applications such as digital audio and video have much more stringent QoS requirements than traditional datagram applications. For a network to deliver QoS guarantees, it must reserve and control resources. Routing is the first step in resource reservation. The routing protocol first finds a path with sufficient resources. Then, the resource setup protocol makes the reservations along the path.

A. Bandwidth in the Cluster Infrastructure

The key resource for multimedia QoS support is bandwidth. Thus, we first must define bandwidth in our cluster infrastructure. Recall that a real-time packet is transmitted every cycle time. For the purpose of real-time connection support, we can define "bandwidth" as the number of real-time connections that can pass through that node. Since, in our scheme, a node can at most transmit one packet per frame, the bandwidth of a node is given by

$$\text{bandwidth} = \left\lfloor \frac{\text{cycle time}}{\text{frame time}} \right\rfloor.$$

The frame time of a cluster depends on how many nodes there are in the cluster, as mentioned in Section III. Fig. 15 shows the slots dedicated to node *i* in the cycle, which correspond to node *i* "bandwidth." For a numerical example, consider

Fig. 15. Node bandwidth.

Fig. 16. Bandwidth of node C in cluster C_1 .

Fig. 16, where the cycle time is 24. Consider cluster C_1 , where frame size is equal to six slots. Thus, the node bandwidth in C_1 is $24/6 = 4$. Since there are three VC's passing through node C , the available bandwidth for node C is one.

B. QoS Routing Scheme

The goal of the bandwidth routing algorithm is to find the shortest path such that the free bandwidth is above the minimum requirement.

To compute the "bandwidth" constrained shortest path, we use the DSDV (destination sequenced distance vector) routing algorithm [15] which was proven to be loop free. Loop freedom follows from the fact that the updates generated by a destination are sequentially numbered. In our shortest path computation, the weight of each link is equal to one (i.e., minimal hop distance routing). The bandwidth constraint is simply accounted for by setting to infinity the weights of all the links to/from a node with zero bandwidth. An advantage of this scheme is to distribute real-time traffic evenly across the network. A cluster with small frame size will allow more connections to pass through it, since it has more "bandwidth" per node.

In addition to load balancing, our routing scheme also supports the alternative paths. This is very important in a mobile environment, where links will fail because of mobility. In such an environment, routing optimality is of secondary importance. The routing protocol must be capable of finding new routes quickly when a topological change destroys existing routes. To this end, we propose to maintain secondary paths which can be used immediately where the primary path fails. In Fig. 17, each node uses the primary route to route its packets. When the first link on the path $(s, N1)$ fails, the secondary path $(s, N2)$ becomes the primary path, and another standby path $(s, N3)$ will be computed, as shown in Fig. 18. It is worth emphasizing

Fig. 17. Standby routing.

Fig. 18. The primary route fails and the standby route becomes the primary route. Another standby route is constructed.

that these routes must use different immediate successors to avoid failing simultaneously.

The secondary (standby) route is easily computed using the DSDV algorithm. Referring to Fig. 17, each neighbor of node S periodically informs S of its distance to destination D . The neighbor with shortest distance yields the primary route. The runner-up yields the secondary route. This scheme guarantees that the first link is different for the two paths. Furthermore, the standby route computation requires no extra table, message exchange, or computation overhead. Also, the standby route is loop free as the primary route is.

V. SYSTEM PERFORMANCE

The multichannel architecture has been evaluated using the MAISIE simulation platform [2]. Several sets of experiments were carried out in order to evaluate the performance as a function of traffic and system parameters, and to compare it with that of other schemes. Most of the simulation experiments share the same network layout and traffic pattern, which are described below.

The channel rate is 800 kbits/s (the nominal rate of the radio under development with the ARPA-sponsored WAMIS project [1]). All data packets (datagram and real-time) are 4 kbits. The preamble for DS-SS acquisition is 500 bits. Thus, data packet transmission time (at 800 kbits/s) is 6 ms. The default *CYCLE* time is 100 ms.

The offered traffic consists of two components: real-time sessions and datagrams. A new real-time session is generated on average every second (Poisson arrival model) between a random pair of nodes. Session duration is exponential with 3 min average. One real-time packet is transmitted every 100 ms. At 4 kbits/packet, this corresponds to 40 kbits/s. Datagrams are also generated between random node pairs, with an average default interarrival time = 100 ms. Datagrams have lower priority than real-time packets on the transmission queue. In order to prevent lockout of datagrams, a fraction

throughput

throughput (pkts/sec)

Fig. 20. Throughput of mix traffic.

α of the *CYCLE* time can be reserved for datagrams. In our experiments, the default value is $\alpha = 0$.

A. Weighted End-to-End Throughput

The link throughput is defined as the sum of the throughputs on the links which are simultaneously active in the network. The performance measure based on link throughput, however, is biased towards a small transmission range since, in this case, there is a large number of short links. There is also a large number of small clusters, many of which may actually be disconnected. In practice, we are more interested in end-to-end throughput rather than single-link throughput, and we would like to maintain connectivity among as many node pairs as possible in the system. To evaluate end-to-end throughput, we generate different topologies with N randomly distributed nodes in a 100×100 square area. We vary the transmission range, and for each value, we obtain different topologies. Then, we average our throughput measures over the random placements. We measure the end-to-end throughput accounting for possible network disconnection:

$$\text{throughput} = \sum_{i=1}^{DC} f_i \frac{LT_i}{L_i}$$

TABLE I
SYSTEM TOPOLOGY ($N = 20$)

	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19
0

19	x																			

TABLE II
PERFORMANCE OF STANDBY ROUTING (MAXIMUM SPEED = 2 F7/S)

	with standby routing	without standby routing
Pkts lost	14 (0.77%)	53 (2.94%)
End-to-End Delay (msec)	290.65	425.45
Throughput (pkts/sec)	9.92	9.70

TABLE III
THE PERFORMANCE OF STANDBY ROUTING (MAXIMUM SPEED = 8 F7/S)

	with standby routing	without standby routing
Pkts lost	21 (1.17%)	104 (5.78%)
End-to-End Delay (msec)	298.80	721.44
Throughput (pkts/sec)	9.88	9.42

More precisely, we denote the following:

- DC total number of disconnected components;
- f_i fraction of node pairs in component $i = (n_i(n_i - 1)/2)/(N(N - 1)/2)$ (n_i : total number of nodes in component i);
- LT_i total link throughput of component i ;
- L_i average path length in component i .

In this formula, LT_i/L_i is the average end-to-end throughput in component i , and f_i is the weight for this throughput. Simulation results are shown in Fig. 19. We find that the optimal transmission range for $N = 30$ is within the interval (35, 45).

B. Real-Time and Datagram Traffic Mix

In the next experiment, we consider the effect of variable real-time load on datagram throughput. The topology connectivity is shown in Table I. Namely, the real-time cycle is allowed to vary from ∞ (i.e., 0 pkt/s) to 100 ms (i.e., 10 pkt/s).

TABLE IV
OVERALL PERFORMANCE COMPARISON (2 FTS)

	PRNET	MACA/PR	Adaptive Clustering	Cluster TDMA
avg VC throughput (pkts/sec)	4.2	9.68	9.89	9.98
total VC throughput (pkts/sec)	15.54	34.65	97.34	107.89
end-to-end delay (ms)	72.02	48.20	254.23	298.15
avg pkt loss per VC	67.70%	3.15%	1.07%	0.01%

TABLE V
OVERALL PERFORMANCE COMPARISON (8 FTS)

	PRNET	MACA/PR	Adaptive Clustering	Cluster TDMA
avg VC throughput (pkts/sec)	4.6	9.69	9.88	9.97
total VC throughput (pkts/sec)	14.54	34.45	95.34	107.70
end-to-end delay (ms)	73.05	66.50	298.80	302.13
avg pkt loss per VC	67.30%	3.07%	1.18%	0.02%

Default values were used for datagram traffic (i.e., $\alpha = 0$ and $CYCLE = 100$ ms). Fig. 20 reports datagram and real-time throughput for varying traffic load. The datagram throughput is the aggregate throughput (sum over all source/destination pairs). The real-time throughput is the average throughput over a session. We note that, because of the priority given to real-time traffic, and because of the $\alpha = 0$ threshold assumption, the datagram throughput decreases very rapidly as the real-time traffic increases. This points out the importance of a careful selection of the threshold α for fair bandwidth sharing.

C. Standby Routing

The following set of experiments evaluates the system performance in a mobile environment with heavy real-time load ($CYCLE = 100$). Due to mobility, real-time packets may be dropped on already established connections during path changes. The goal of this experiment is to assess the improvement introduced by the "standby" routing feature, i.e., the availability of an alternate route in case the preferred route fails. This feature is of critical importance when stations are mobile. In particular, it is expected to reduce loss rate. Two experiments were run, with speed 2 and 8 fts, respectively. Tables II and III show the results. Standby routing reduces packet loss by more than 50% in both cases.

D. Scheme Comparison Synopsis

Tables IV and V compare the proposed adaptive cluster scheme with various schemes which have appeared in the literature, namely, PRNET [17], MACA/PR [14], and cluster TDMA [7]. PRNET is a multihop packet radio network which uses CSMA for channel access. Neither clustering nor slot synchronization is needed. No separate initialization procedure is required. A simple Bellman-Ford distance vector is used. Real-time traffic delivery is made more reliable by the use of "duct routing" [17], namely, multiple copies of the same packet are carried in parallel on alternate paths to destination. MACA/PR uses the IEEE 802.11 (RTS/CTS) access scheme. It implements QoS routing and bandwidth reservations using

a scheme similar to the one proposed here. It does not use clustering, code separation, or slot synchronization. In this respect, it is totally asynchronous, like PRNET. Cluster TDMA is an earlier, more complex version of the scheme presented here with more overhead. The key differences are clusterhead-based clustering, fixed TDMA control slots and "on-demand" data slots in the frame, use of multiple codes within each cluster, and frame synchronization (i.e., slot alignment) across frames.

In this experiment, $CYCLE = 100$. The schemes are ordered by increasing implementation complexity (from the totally asynchronous PRNET to the highly organized cluster TDMA). Both throughput per connection and aggregate throughput are compared. The performance of our proposed adaptive cluster is very similar to that of cluster TDMA. This is of quite some interest since adaptive cluster uses code separation, but does not require intercluster synchronization (it only requires intracluster synchronization). Performance is only moderately degraded by speed increase. MACA/PR appears to provide an attractive compromise between throughput efficiency and simplicity of implementation. On the positive side, MACA/PR exhibits the lowest end-to-end delay (which is critical for some real-time applications such as voice). On the negative side, MACA/PR cannot achieve the aggregate throughput efficiency of cluster-type solutions (which benefit from code separation).

VI. CONCLUSIONS

We have presented an adaptive clustering architecture for multimedia support in a multihop mobile network. This architecture is not constrained by a fixed infrastructure; rather, it can be deployed in an environment without infrastructure at all. It can also tolerate mobility well because of the robustness of our adaptive cluster algorithm.

In order to reduce control overhead and to overcome the limitation of the number of orthogonal codes, we use only one code within each cluster. Packet transmissions by data sources and real-time sources are interwoven, with top priority given to real-time sources. Within each cluster, TDMA

permits us to reserve bandwidth for real-time traffic. Taking advantage of spread spectrum, adjacent clusters can transmit at the same time on different codes. Simulation experiments have identified key tradeoffs between transmission range and throughput performance, and have shown the advantages of code separation and spatial reuse. The performance of the proposed cluster scheme is similar to that of cluster TDMA [7], with less implementation complexity (less burdened by synchronization requirements).

Chunhung Richard Lin was born in Kaohsiung, Taiwan. He received the B.S. and M.S. degrees from the Department of Computer Science and Information Engineering, National Taiwan University, in 1987 and 1989, respectively, and the Ph.D. degree from the Department of Computer Science, University of California, Los Angeles, (UCLA) in 1996.

Currently, he is an Associate Professor in the Department of Computer Science and Information Engineering, National Chung Cheng University, Taiwan. His research interests include the design and control of personal communication service networks, mobile computing, performance evaluation, and distributed simulation.

Mario Gerla received the graduate degree in electrical engineering from Politecnico di Milano, Italy, in 1966 and the M.S. and Ph.D. degrees in computer science from the University of California, Los Angeles, (UCLA) in 1970 and 1973, respectively.

From 1973 to 1976, he was a Manager at the Network Analysis Corporation, Glen Cove, NY, where he was involved in several computer network design projects for both government and industry, including performance analysis and topological updating of the ARPANET under a contract from DoD. From 1976 to 1977, he was with Tran Telcommunication, Los Angeles, CA, where he participated in the development of an integrated packet and circuit network. Since 1977, he has been on the Faculty of the Department of Computer Science, UCLA. His research interests include the design, performance evaluation, and control of distributed computer communication systems and networks. His current research projects cover the following areas: topology design and bandwidth allocation in ATM networks, design and implementation of optical interconnects for supercomputer applications, design and performance evaluation of air/ground wireless communications for the Aeronautical Telecommunications Network, and network protocol design and implementation for a mobile, integrated services wireless radio network.
